**Abstract:** Dehydration and fluid circulation are integral parts of subduction tectonics that govern the dynamics of the wedge mantle. The knowledge of the elastic behavior of aqueous fluid is crucial to understand the fluid–rock interactions in the mantle through velocity profiles. In this study, we investigated the elastic wave velocities of chlorite at high pressure beyond its dehydrating temperature, simulating the progressive dehydration of hydrous minerals in subduction zones. The dehydration resulted in an 8% increase in compressional ( $V_p$ ) and a 5% decrease in shear wave ( $V_s$ ) velocities at 950 K. The increase in  $V_p$  can be attributed to the stiffening of the sample due to the formation of secondary mineral phases followed by the dehydration of chlorite. The fluid-bearing samples exhibited  $V_p/V_s$  of 2.45 at 950 K. These seismic parameters are notably different from the major mantle minerals or hydrous silicate melts and provide unique seismic criteria for detecting mantle fluids through seismic tomography.

## 1. Introduction

The dehydration of subducted hydrous minerals releases a flux of fluid into the wedge mantle [1]. The aqueous fluid entering the overlying mantle influences geochemical and geophysical processes, such as arc melting [2], mantle metasomatism [3,4], intermediate-depth seismicity [5,6], and the dynamics of the wedge-mantle flow [7]. The determination of the physical state of slab fluid can constrain the thermal state of the slab as melting, and dehydration reactions occur at different temperatures. Detection and differentiation of aqueous fluid and silicate melt and how they migrate and interact with the overlying mantle are therefore fundamental to the understanding of the subduction zone system [8].

Seismic velocities, anelastic attenuation, and seismic anisotropy are the key parameters that provide information on physical and chemical interactions between the slab and the mantle [8]. The low velocity and high attenuation (low- $Q$ ) in subduction zones have often been interpreted as an indication of the presence of a liquid phase [8]. This interpretation comes from the notion that the shearing motion cannot be transmitted through a liquid, as it may slow down the compressional ( $P$ ) waves and hinder the propagation of shear ( $S$ ) waves and attenuate [9–11]. The attenuation is often described by the seismic attenuation factor ( $Q^{-1}$ ), which depends on the temperature, composition, fluid/melt fraction, fluid/melt geometry, and grain size [12,13], and provides robust constraints on subduction zone components [14].

The seismic structures of most subduction systems have been well documented, and the high-resolution seismic tomography images [14], receiver function method [15],

and seismic refraction methods allow the detection of seismic anomalies with great accuracy [16]. The prior knowledge of the elastic properties of major mantle mineral phases provides the basic framework for the interpretation of seismic parameters [17] obtained through inversion methods. The available criteria allow the identification of solid from liquid phases [18–22] or distinguish hydrous minerals from nominally anhydrous minerals [15,22–24]. However, there are no robust seismic parameters to identify aqueous fluids. At present, the interpretation of the presence of fluid is based on indirect observations, mainly through comparison of the seismic anomaly with the depth of dehydration, temperature profile, and proximity to the volcanic activity [15,25–27]. Despite the importance of seismic properties of fluid-bearing systems that have long been identified [15,24,28], the elastic velocity data on aqueous fluids have not been determined experimentally, partly due to the challenging nature of investigating fluid-bearing systems at high pressure. With the notable absence of seismic parameters of aqueous fluids, the interpretation of seismic anomalies in subduction zones remains an uncertain exercise.

The present study investigated the elastic properties of the dehydration-induced fluid occurring in subduction zones. Using high-pressure ultrasonic measurements, we have determined elastic wave velocities of chlorite and dehydrating fluids at 1.8 and 3.8 GPa with increasing temperatures, simulating the progressive dehydration in the subducting slab. Chlorite ( $\text{Mg, Fe})_5\text{Al}(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH})_8$ , is one of the major hydrous phases stable in subducting ultramafic, mafic, and sediment lithologies [1,29–31]. The presence of chlorite in both the subducting slab and the hydrated mantle wedge presents a unique opportunity to investigate diverse dehydration scenarios in subduction zones.

## 2. Materials and Methods

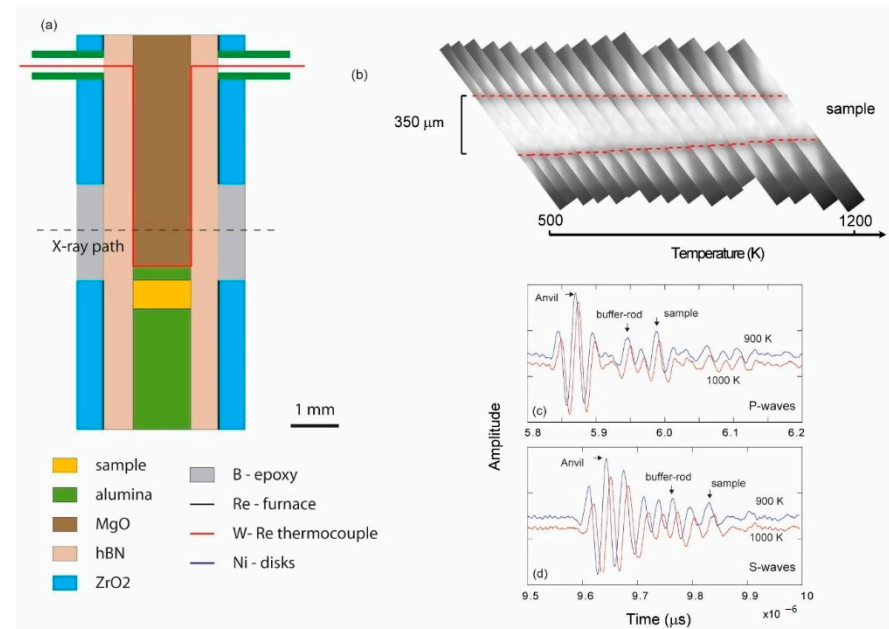

### 2.1. Sample Characterization

In this study, we measured the elastic wave velocities of natural chlorite with  $(\text{Mg}_{3.77}\text{Fe}_{1.23})\text{Al}(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH})_8$  stoichiometry at conditions representative to the mantle wedge and subduction zone settings. The natural chlorite sample used in this study was from the Ambatomainty region in Madagascar. The chemical composition of chlorite was determined by electron probe microanalysis (EPMA) using a Cameca SxFiveTactis electron microprobe, operating at an accelerating voltage of 15 kV and a beam current of 20 nA. The samples were further characterized by powder X-ray diffraction (XRD). After each experiment, cross-sections of run products were investigated using energy-dispersive X-ray spectroscopy (EDS) chemical mapping, using a Jeol JSM–5910 LV scanning electron microscope.

### 2.2. High-Pressure, High-Temperature Experiments

High-pressure and high-temperature conditions were generated using the 1200-ton DIA-type multi-anvil module at the PSICHE beamline in SOLEIL Synchrotron in France. For experiments conducted at 1.8 and 3.8 GPa, we used an octahedral pressure medium composed of  $\text{MgO} + \text{Cr}_2\text{O}_3$  in a 10/4 multi-anvil configuration (Figure 1a). Cylindrical core samples of 1.2 mm diameter and 0.5 mm in length were placed in a hexagonal boron nitride (hBN) capsule, which electrically insulated the sample from the furnace during the measurements. The high-purity hBN, sintered at high temperature and pressure without a boron oxide ( $\text{B}_2\text{O}_3$ ) binder (BNHP-FINAL Advanced Materials), ensures that there were no  $\text{B}_2\text{O}_3$  forming reactions with the aqueous fluids. Two Ni disks (10  $\mu\text{m}$ ) placed at the top and bottom of the sample served as metal markers for X-ray radiography images, which were used for the measurement of the sample lengths using the radiography images (Figure 1b). The presence of Ni was expected to maintain the oxygen fugacity of the sample close to the Ni-NiO buffer. A  $\text{W}_{95}\text{Re}_5$ - $\text{W}_{74}\text{Re}_{26}$  thermocouple junction was placed at one side of the sample, which monitored the temperature. A dense  $\text{Al}_2\text{O}_3$  buffer rod was placed between one of the tungsten carbide (WC) anvil truncations and the sample, to enhance the propagation of elastic waves and to provide sufficient impedance contrast to reflect ultrasonic waves at the buffer rod–sample interface. We placed a 0.3 mm thick alumina disc on the opposite end of the sample to maintain the sample geometry (Figure 1a). Both

ends of the anvil, the alumina buffer rod, and the samples were mirror-polished to enhance mechanical contacts. All ceramic parts of the cell assembly, including the pressure medium, were fired at 1273 K prior to their assemblage, to remove any adsorbed moisture, and were kept at 400 K in a high-vacuum furnace ( $10^{-2}$  Torr) before assembling the experiment.

**Figure 1.** (a) Schematic assembly configuration of the multi-anvil cell assembly (before compression) used for the sound wave velocity measurements. (b) The stacked radiography images of the sample with increasing temperature at 3.8 GPa. The red dashed lines show the thickness of the sample. Examples of the ultrasonic signals recorded at 40 MHz for P-waves (c), and S-waves (d) recorded at 900 and 1000 K, before and after the dehydration of chlorite.

### 2.3. Seismic Wave Velocity Measurements

Sound wave velocities of the samples were measured using the ultrasonic interferometry technique [32]. In this method, electrical signals of sine waves of 20–50 MHz (3–5 cycles) with  $V_{\text{peak-to-peak}}$  of 5 V were generated by an arbitrary waveform generator (Tektronix AFG3101C); they were then converted to primary ( $V_p$ ) and secondary ( $V_s$ ) waves by a  $10^\circ$  Y-cut LiNbO<sub>3</sub> piezoelectric transducer attached to the mirror-polished truncated corner of a WC anvil. The resonant frequency of the transducer is 50 MHz for compressional waves (P-waves) and 30 MHz for shear waves (S-waves). Elastic waves propagated through the tungsten carbide (WC) anvil, alumina buffer rod (BR), and the sample, and were reflected at the interfaces between the anvil-BR, the BR-sample, and the sample electrode (Figure 1c,d). The reflected elastic echo waves were converted back to electrical signals by the transducer and captured by a Tektronix DPO 5140 Digital Phosphor Oscilloscope at a rate of  $5 \times 10^9$  sample/s. Signals at 20, 30, 40, and 50 MHz were recorded at each temperature step. The two-way travel time for the sound waves propagating through the sample was determined by the time difference between the arrivals of the echoes from the BR-sample interface and the sample-backing material interface by the pulse-echo overlap method [32]. Sample lengths at each temperature were determined using the X-ray radiography images (Figure 1b). Experimental measurements of velocity are subject to uncertainties originating from the estimation of temperature, pressure, sample dimensions, and fitting errors. Errors have been estimated to be 2.0% ( $2\sigma$ ).

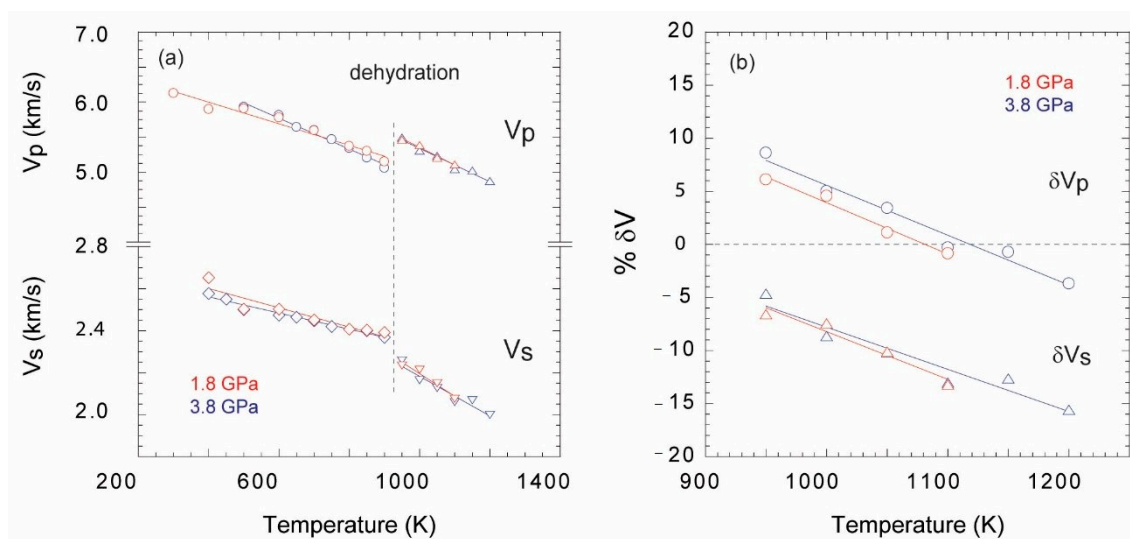

### 2.4. Synchrotron Experiments

Energy-dispersive X-ray diffraction was used to determine the sample pressure and verify the sample state. Diffraction was performed in an energy-dispersive mode using a CAESAR-type diffraction detector system [33]. The characteristics of the beam-line were

discussed in previous studies [34–36]. Simultaneously, we acquired radiographic images for the determination of the sample lengths, yielding accurate quantitative determination of elastic velocity at each temperature (Figure 1b). The focused beam configuration (in vertical) allowed each image to be assembled by scanning the press in front of the beam. This had the advantage of producing almost flat-field corrected images, a feature usually not available when using multi-anvil modules.

### 3. Results

The ultrasound wave velocities of polycrystalline aggregates of natural chlorite were obtained in situ at pressures of 1.8 and 3.8 GPa and temperatures up to 1200 K (Figure 2). The increase in temperature incurred a gradual decrease in both  $V_p$  and  $v_s$  in chlorite, consistent with the softening of bulk and shear moduli with temperature. However, temperature appeared to have a more pronounced effect on  $V_p$  than it had on  $v_s$ . Compared to major mantle minerals, the  $V_p$  and  $v_s$  of chlorite appeared to be significantly lower, 5 km/s and 2.5 km/s respectively, at 900 K. We observed that the increase in pressure had a negligible effect on both compressional and shear wave velocities.

**Figure 2.** (a) Primary ( $V_p$ ) and secondary ( $v_s$ ) wave velocities as a function of temperature at 1.8 and 3.8 GPa. (b) The % drop in velocity ( $\delta V_p$ ,  $\delta v_s$ ) upon dehydration at 1.8 and 3.8 GPa compared to chlorite before dehydration. The lines are the linear fits through data points. Uncertainties in velocity estimations are estimated to be less than 2.0% ( $2\sigma$ ), smaller than the symbol size.

The dehydration of chlorite exhibited a unique velocity behavior which resulted in an increase in  $V_p$  and decrease in  $v_s$ . Upon dehydration, it was expected that both  $V_p$  and  $v_s$  would decrease at the dehydration and subsequent release of fluid, following the characteristic elastic wave velocity behavior for liquids [18,20,37]. The increase in temperature beyond 900 K prompted a marked change of velocities, as  $V_p$  increased from 5.1 to 5.5 km/s, and  $v_s$  decreased from 2.37 to 2.23 km/s at 950 K. The change in velocities corresponded to an 8% increase in  $V_p$  and a 5% decrease in  $v_s$ , relative to the normalized velocities in chlorite prior to dehydration (Figure 2b).

Analyses of recovered experimental run products after sound wave velocity measurements confirmed the partial dehydration of chlorite at high temperatures, which produced olivine, pyrope-garnet, hercynite spinel ( $\text{Fe}_2(\text{Mg}, \text{Al})\text{O}_4$ ) at 1.8 GPa, and the stability of olivine and Mg-sursassit at 3.8 GPa was consistent with previous studies [38,39] (Figure 3). We observed a higher proportion of Mg-sursassite at 3.8 GPa, which indicated partial dehydration of chlorite and stability of an intermediate hydrous phase [38]. The partially dehydrated chlorite retained the relict preferred orientation perpendicular to the compression axis.

## 4. Discussion

### 4.1. Elastic Wave Velocities

The measured elastic wave velocities of Fe-bearing chlorite ( $\text{Mg}_{3.77}\text{Fe}_{1.23}\text{Al}(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH})_8$ ) in this study indicated a ~20% decrease in  $V_p$  and ~38% decrease in  $V_s$  relative to the ambient temperature velocities of Mg-endmember chlorite  $\text{Mg}_5\text{Al}(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH})_8$  obtained using static density functional theory (DFT) [40]. The decrease in  $V_p$  and  $v_s$  with the incorporation of Fe in chlorite was in agreement with the effect that Fe had on elastic wave velocities of mantle minerals [41–45]. The incorporation of Fe resulted in an increase in density from  $2.60 \text{ g cm}^{-3}$  of Fe-free variety [40] to  $2.761 \text{ g cm}^{-3}$  in our sample, which represented a 6% increase in density at ambient conditions. While the incorporation of Fe affected both elastic moduli and the density, it has been shown that the increase in density due to the increase in Fe contents was responsible for the observed low velocities in Fe-bearing minerals compared to their Fe-free varieties [46].

The unique increase in  $V_p$  at the dehydration of chlorite reflected important mineralogical changes that occurred in the sample. Unlike melting, in which mineral phases are consumed to produce melt, dehydration stabilizes a suite of solid minerals together with the fluid phase. We attributed the unique increase in  $V_p$  during dehydration of chlorite to the increase in the stiffness of the sample due to the crystallization of secondary mineral phases, which affected the compressibility, compensating for the velocity decrease by the fluid phase. The increase in  $V_p$  can be explained by dehydration of only 10 vol.% of chlorite (Figure 4). Further dehydration increased the volume fraction of fluid in the sample, gradually masking the effect of nominally anhydrous minerals, garnet, olivine, spinel, as seen by the decrease in  $V_p$  with increasing temperature (Figure 4).

**Figure 4.** P-wave velocity compared with the vol.% of chlorite dehydration. The  $V_p$  vs. temperature diagram showing the P-wave velocity for chlorite and dehydration products. The black dashed line indicates the  $V_p$  of chlorite before dehydration, extrapolated to high temperatures. The purple solid line indicates the P-wave velocity of a mixture of olivine [47], garnet [48], and spinel [49], computed for 3:1:1 proportion based on the dehydration reaction  $2\text{chl} = 3\text{ol} + \text{gt} + \text{spl} + 8\text{H}_2\text{O}$ . Blue dashed lines indicate the linear mix between the velocity of chlorite and the  $(3\text{ol} + \text{gt} + \text{spl})$  without taking into account the velocity effect of fluid. The numbers next to dashed lines indicate the fraction chlorite dehydrated producing the  $(\text{ol} + \text{gt} + \text{spl})$ . The red and blue solid lines indicate linear fits through the  $V_p$  data points of chlorite measured at 1.8 and 3.8 GPa, respectively.

#### 4.2. The Velocity Ratio ( $V_p/V_s$ ) in Chlorite and Dehydrating Fluids

The velocity ratio  $V_p/V_s$  is frequently used to interpret composition, structure, and dynamic properties in the Earth's interior [50–52]. For major upper mantle minerals, the ratio varies within a narrow range of 1.7–1.8, with garnet showing the highest value around 1.8 [52]. The velocity ratios of major mantle minerals show a general tendency to increase with increasing pressure and temperature. In this study, we observed a 13% increase in the  $V_p/V_s$  ratio, from 2.14 at 900 K to 2.45 at 950 K, as a result of the dehydration of chlorite. After dehydration, the value remained nearly constant, while further increases occurred in temperatures up to 1200 K (Figure 5). The unusually high  $V_p/V_s$  ratio of chlorite was consistent with the previous DFT calculations [40]. The progressive decrease in velocity ratio in chlorite with increasing temperature prior to the dehydration may be linked to the decrease in the principal elastic moduli  $C_{33}$  component, due to the development of preferred orientation in chlorite perpendicular to the principal compression axis. Low elastic wave velocities and a high  $V_p/V_s$  ratio have also been reported for antigorite [23], another principal hydrous mineral in subduction zones.

While the velocity ratio of major mantle minerals varies in a narrow range, the parameter has been considered as a reliable seismic tool to distinguish liquid phases from solid minerals. The velocity ratio has been used to predict the melting in the asthenosphere–lithosphere boundary, at subduction zones, and at the  $D''$  layer at the core–mantle boundary region [18,53,54]. The iron-enriched minerals observed at the core–mantle boundary region appeared to have anomalous seismic velocities, while the velocity ratio has been used to

predict chemical interactions between the metal–liquid outer core and the overlying solid mantle [55].

**Figure 5.** The  $V_p/V_s$  ratios of chlorite and dehydrating fluid at 1.8 and 3.8 GPa. The  $V_p/V_s$  of major mantle phases, olivine, garnet, clinopyroxene (cpx), orthopyroxene (opx), are shown for comparison [47]. Diamond symbols indicate antigorite [23] at 1.8 GPa (red) and 3.8 GPa (blue) at 300 K. The blue shaded line indicates the  $V_p/V_s$  of basaltic melt [18] for increasing melt fraction. The faded blue area corresponds to the dehydrating fluid. The red and blue dashed-lines are the second-order polynomial fits through data points.

In the Earth, melts or aqueous fluids occur in small quantities (a few vol.%), distributed along grain boundaries of the matrix minerals. The presence of a small amount of liquid shuts off the direct travel paths for wave propagations through shearing motion thereby effectively increasing the travel time and decreasing  $V_s$ . The compressional wave velocity is decreased due to the absence of the shear component; however, compressional waves could still travel through liquid media. Therefore, a general increase in  $V_p/V_s$  is expected for liquid phases due to the large drop in  $V_s$ . This tendency has been demonstrated by recent experimental studies [18,20,21], showing a systematic increase in  $V_p/V_s$  with increasing melt fraction.

The elastic wave velocity of aqueous fluids has not been investigated prior to this study. In this study, we have shown for the first time that the  $V_p/V_s$  ratio of the fluid-bearing sample increased sharply upon dehydration from 2.15 at 900 K to 2.45 at 950 K (Figure 5). Despite the increase in temperature, the fluid fraction appears to have had a negligible influence on the ratio. A higher  $V_p/V_s$  ratio was observed for the hydrous silicate melt [18,20]. Nevertheless, the  $V_p/V_s$  of hydrous basaltic melt was strongly dependent on the melt fraction, and a  $V_p/V_s$  of less than 2 can be expected for the geologically relevant melt fractions in the Earth [18]. Thus, the  $V_p/V_s$  ratio of about 2.4 could be a robust indicator of the presence of fluid in the mantle.

#### 4.3. The Effect of Dehydration on the Amplitudes of P- and S-Wave Echoes

The amplitudes of both P- and S-wave echoes exhibited unusual behavior above 900 K, closely following the dehydration temperature of chlorite (Figure 6a,b). For example, the amplitude of the first echo of P-waves at 3.8 GPa was unaffected by the onset of dehydration

at 900 K; however, an 8.5% decrease in the amplitude relative to the values normalized to the chlorite before dehydration was observed at around 1050 K. The amplitude of the first echo of P-wave of chlorite at 1.8 GPa, on the other hand, decreased by 50%, then recovered to the initial value and continued to decrease with increasing temperature. Amplitudes of the 1st echo of S-waves of 1.8 and 3.8 GPa samples followed a decreasing trend, with chlorite at 3.8 GPa exhibiting a steep change compared to the measurements at 1.8 GPa.

**Figure 6.** The % change of amplitude of P- (a) and S- (b) waves relative to the amplitude for the chlorite before dehydration. Blue and red lines are for 1.8 and 3.8 GPa respectively. The vertical dashed line indicates the dehydration temperature observed for chlorite. (c) The change of amplitudes in the 1st, 2nd, and 3rd echos of the P-waves at 3.8 GPa. The blue and red lines in panels (a) and (b) are the cubic-spline fits through data points.

The decrease in wave amplitudes mostly depends on the reflectance (and transmittance) of waves at the interfaces between sample and alumina. Reflectance and transmittance of waves at interface depend on the contrast of acoustic impedance. The sharp decrease in the amplitude of P- and S-waves can be correlated to the release of aqueous fluid into the sample, which may change the acoustic impedance of the fluid-bearing sample. The unique increase in amplitude after the initial drop may be related to the growth of olivine, garnet, and spinel crystals in the sample, which may increase the bulk density of the sample relative to chlorite (Figure 6a). However, the attenuation in hydrous minerals during progressive dehydration appears to be governed by the fine balance between the amount of aqueous fluid present in the sample and the increase in bulk density due to the appearance of nominally anhydrous mineral phases. The shear waves lose more energy compared to P-waves, due to scattering at grain boundaries, especially when the grain boundaries contain a liquid phase. The decrease in the amplitudes of S-waves observed in our study was consistent with the continuous release of fluid into the sample with increasing temperature (Figure 6b).

The 1st, 2nd, and 3rd echos observed for p-waves in our sample at 3.8 GPa exhibited a unique behavior, indicating a sudden drop in amplitude at three different temperatures (Figure 6c). The magnitude of the drop in amplitude and the temperature at which the maximum drop occurred decreased from the 1st echo to the 3rd echo. While we could not offer a definitive explanation, we propose that this observation could be due to the cumulative effect of sound waves traveling multiple times through the fluid-bearing media.

#### 4.4. Geophysical Implications

Mantle wedges, where increased fluid activities can be expected, are often characterized by anomalous seismic properties. The low velocity and high  $V_p/V_s$  have often been interpreted as an indication of the presence of hydrous minerals such as serpentine and chlorite [40,56]. In light of the new data obtained in this study, we can explore low-velocity and high  $V_p/V_s$  regions to track fluid migration in mantle wedges.

The most compelling observation comes from the absolute  $V_p/V_s$  ratios obtained using the 3D seismic tomography at the central Chile–Argentina subduction zone [57] and the south-central Chilean subduction zone [58], where they emphasize high  $V_p/V_s$  ratios

at the mantle depth of about 50 km. It has been speculated that a Vp/Vs ratio of around two, may indicate the presence of frozen pooled-melt [57] in these subduction systems. However, the depth at which the anomaly is observed (~50 km) may not correspond to the arc melting. The depth at which the seismic anomaly has been observed also coincides with the high conductivity anomaly observed for the Andean subduction system [59,60]. Such high conductivities can be attributed to the presence of aqueous fluids [61]. We interpreted the low-velocity anomaly and the high Vp/Vs ratio observed in the Chile and Argentina subduction systems as some of the best examples of the presence of aqueous fluid in subduction systems. The increase in  $\delta V_p$ , decrease in  $\delta V_s$ , and the high Vp/Vs ratio around 2.4 can, thus, be used to define aqueous fluids in subduction zones. This study would lay the foundation for tracking dehydrating fluid in the mantle through a high-resolution seismic tomography method.

**Author Contributions:** G.M. designed the study. G.M. and J.C. performed the experiments and analyzed data. G.M. wrote the manuscript. N.G. and A.K. assisted with the synchrotron set-up at the PSICHE beamline. All authors have read and agreed to the published version of the manuscript.
